SIMPON'S REVERSAL PARADOX AND COST ALLOCATION

SHYAM SUNDER

Allocation of indirect costs among products sometimes yields a paradoxical result that unit cost for each product may increase under one method of allocation and may decrease for each product under another method. The Stalcup Paper Company[1] case illustrated such behaviour of costs and at the same time, provides an accounting example of Simpson's Reversal Paradox Simpson (1951), which Blyth (1972) discussed in the statistics literature. As with other paradoxes, this cost allocation paradox disappears upon closer scrutiny. This paper examines the properties of allocated costs in order to arrive at an intuitive understanding of the results. The relationship of the cost allocation problem to Simpson's Paradox and the implications of the analysis for cost control are briefly discussed. Necessary and sufficient condition for occurence of the Paradox is also given.

Cost Allocation Paradox

Table 1 shows the cost figures for a two-product department for two adjacent accounting periods.[2] There are only two types of costs: direct labour costs which have remained unchanged from period 1 to period 2 ($6.25/lb. for product A and $0.625/lb. for product B, and indirect costs whose total has also remained unchanged at $26,000. Production of A decreased from 3,200 to 2,400 pounds and production of B increased from 300 to 2,400 pounds over the two periods. When indirect costs are allocated on the basis of direct labour dollars, unit costs increase from $14.18 to $16.10 for product A and from $1.418 to $1.61 for product . It would seem that the efficiency of the production process, as measured by these costs has deteriorated. Yet, when the same costs are allocated on the basis of the units (weight) of each product, it is found that the unit costs of <u>both</u> products have <u>decreased</u> over the same period (from \$12.75 to \$11.67 for A and from \$7.125 to \$6.045 for B), and on the basis of costs alone, one is tempted to conclude that the efficiency of production process has gone up rather than gone down. How could this be?

The Stalcup Paper Company case provides an accounting example of Simpson's Reversal Paradox (Simpson (1951), Blyth (1972) is stated as follows:

(1) It is possible to have

$$P(A|B) > P(A|B')$$

and have at the same time both

$$P(A|B \text{ and } C) \leq P(A|B' \text{ and } C)$$

$$P(A|B \text{ and } C') \leq P(A|B' \text{ and } C')$$

where $P(A|B)$ is probability of event A conditional on event B and prime indicates complements.

Consider two examples of the paradox. The first example is by Blyth (1972) in which the survival rates of patients given standard and a new medical treatment are compared in the table 2.

Because only 11% of the patients given new treatment survived, as compared to 46% under the standard treatment, it would seem that the new treatment is inferior to the standard. However, when we consider the table 3 which gives the disaggregated data for two types of patients, this conclusion is reversed, and the new treatment appears to be definitely superior. For C-type patients survival rate under new treatment doubled from 5 to 10 percent and for the C'-type patients it almost doubled from 50 to 95 percent.

The reason for the reversal is that, while 10 out of every 11 patients of type C are selected for the new treatment, only one out of every 101 patients of type C' are given the new treatment. If event A is survival and B is new treatment, we have the Simpson's Paradox as stated in (1):

$$P(A|B) = 0.11 < P(A|B') = 0.46$$

While $$P(A|BC) = 0.10 > P(A|B'C) = 0.05$$

and $$P(A|BC') = 0.95 > P(A|B'C') = 0.50.$$

ntuitively we tend to assume that $P(A|B)$ and $P(A|B')$ are <u>equally</u> eighted averages of $P(A|BC)$ and $P(A|BC')$ and of $P(A|B'C)$ and $P(A|B'C')$ respectively. However, because

2) $$P(A|B) = P(C|B) \cdot P(A|BC) + P(C'|B) \cdot P(A|BC')$$

$$P(A|B') = P(C|B') \cdot P(A|B'C) + (P(C'|B') \cdot P(A|B'C')$$

nd the weights $P(C|B)$, $P(C'|B)$, $P(C|B')$ and $P(C'|B')$ are given to e 100/101, 1/101, 1/11 and 10/11 respectively by the sampling scheme specified above, it can easily be confirmed that

$$0.11 = \frac{100}{101} \cdot 0.10 + \frac{1}{101} \cdot 0.95$$

$$0.46 = \frac{1}{11} \cdot 0.05 + \frac{10}{11} \cdot 0.95$$

A second example of the paradox is provided by Gardner (1976). Table 4

Given the number of black and white chips in each box, if one were to maximize the probability of drawing a black chip, Box 1 is preferred over Box 2 (since 5/11 > 3/7) and Box 3 is preferred over Box 4 (since 6/9 > 9/14).

Yet, when the contents of Boxes 1 and 3 are combined and the contents of Boxes 2 and 4 are combined, the second combination is preferred over the first (since 12/21 > 11/20). Algebraically, the paradox is stated in terms of positive numbers.

It is possible to have

$$\frac{a+b}{c+d} > \frac{e+f}{g+h}$$

and have at the same time both

$$\frac{a}{c} \leq \frac{e}{g}$$

and

$$\frac{b}{d} \leq \frac{f}{h}$$

Equivalence of (1) and (3) can be seen immediately by setting

$$a = P(C|B) \cdot P(A|BC)$$
$$b = P(C'|B) \cdot P(A|BC')$$
$$c = P(C|B)$$
$$d = P(C'|B)$$
$$e = P(C|B') \cdot P(A|B'C)$$
$$f = P(C'|B') \cdot P(A|B'C').$$
$$g = P(C|B')$$
$$h = P(C'|B')$$

The cost allocation paradox mentioned above in another case Simpson's Paradox. Let TC_i^t be the total indirect costs allo- ed to product i during period t on the bas; of direct labor ts and q_I^t be the quantity of product i produced in period t. Then allocated unit cost is given by TC_i^t/q_i^t. If indirect costs are allocated on the basis of quantity instead of direct labor, the unit cost of period t is given by $\sum_i TC_i^t/\sum_i q_i^t$ and is the same for all i. In the example given earlier, the unit costs allocated on the basis of quantities were higher in the first year than in the second, i.e.,

$$(4a) \qquad \frac{TC_1^1 + TC_2^1}{q_1^1 + q_2^1} > \frac{TC_1^2 + TC_2^2}{q_1^2 + q_2^2}$$

and yet the unit costs allocated on the basis of direct labor costs were lower in the first period for each product, i.e.,

$$(4b) \qquad \frac{TC_1^1}{q_1^1} < \frac{TC_1^2}{q_1^2}$$

and

$$\frac{TC_2^1}{q_2^1} < \frac{TC_2^2}{q_2^2}$$

It is easy to see that this is equivalent (3) above.

For an intuitive understanding of the results, let us consider a simple model where a fixed indirect cost[3] F is allocated between two products, 1 and 2, on the basis of the amount of a given resource used directly in producing each product. It takes production of p_1 units or product 1 to use up one unit of the basis resource. Similarly, production of p_2 units of product 2 requires, among other things, one unit of the basis resource. In order to produce q_1 units of product 1 and q_2 units of product 2, [illegible] $(q_1/p_1 + q_2/p_2)$ units of basis resource are used up[4]. Thus, total cost F is allocated between the two products as follows:

(5) $$TC_1 = \frac{q_1p_2}{q_1p_2 + q_2p_1} \cdot F$$

(6) $$TC_2 = \frac{q_2p_1}{q_1p_2 + q_2p_1} \cdot F$$

The corresponding per-unit (average) allocated costs are

(7) $$c_1 = \frac{p_2}{q_1p_2 + q_2p_1} \cdot F$$

(8) $$c_2 = \frac{p_1}{q_1p_2 + q_2p_1} \cdot F$$

Consider the behavior of total and per-unit allocated costs as the sum of q_1 and q_2 is held constant at, say, k units and the product-mix is changed by substituting a unit of one product for a unit of the other. The behavior of total costs allocated to each product, TC_1 and TC_2, when the product mix is altered from 100 percent of product 1 to 100 of product 2 is shown in Figure 1.

Figure 1 is a box diagram with origins for products 1 and 2 in the lower left and upper right corners, respectively. Any point $\underline{x}_1$ on the line joining the two corners represents a product-mix of a_1 unit of product 1 and $a_2 = k-a_1$ units of product 2 to which costs of b_1 and $b_2 = F-b_1$, respectively, are allocated.

The shape of the curve joining the lower left and upper right corners is determined by differentiating (5) with respect to q_1

(9) $$\frac{dTC_1}{dq_1} = \frac{p_1p_2}{(q_1p_2+q_2p_1)^2} \cdot F.k \text{ where } k = (q_1 + q_2)$$

The slope of TC_1 is always positive with value p_2F/p_1k at the lower left corner and p_1F/p_2k at the upper right corner. If $p_1 > p_2$, the slope increases from left to right and we obtain the shape of the cost allocation curve given in Figure 2. If $p_1 = p_2$, the slope remains constant throughout and the allocation curve is the straight line joining the two corners. Finally, if $p_1 < p_2$, the curve is bent in the opposite direction as shown in Figure 2.

It is the curvature of the cost allocation curve, when p_1 and p_2 are not equal that gives rise to the apparently paradoxical behavior of per-unit allocated costs. This can be seen immediately from an examination of Figure 3 in which per-unit allocated costs for any product mix are given by the slope of the line joining the point on the cost allocation curve to the appropriate origin. Take a product mix x_1 on an allocation curve for $p_1 > p_2$ and consider a change to product mix x_2 on the same allocation curve The unit cost of Product 1 increases from the tangent of angle x_1Ok to the tangent of angle x_2Ok. At the same time, the unit cost of Product 2 increases from the tangent of angle $x_1O'k'$ to the tangent of angle $x_2O'k'$. Because of the convexity of the allocation curve throughout (increasing slope), any rightward movement in product mix must result in increased unit costs for <u>both</u> products, even though the total allocated costs increase for the product whose share increases. Conversely, any leftward movement must result in a decrease in the unit costs for <u>both</u> products, eventhough the total allocated costs are shifted from Product 1 to Product 2.

Figure 4 shows similar results for cost allocation on the basis of another resource for which $p_1 < p_2$ and the cost allocation curve is concave (decreasing slope). A rightward movement in product mix results in a decrease and a leftward movement results in an increase in the unit costs for both products.

The behavior of marginal and average (per-unit) allocated costs as a function of the product-mix is shown in Figure 5 (a) and (b). In Figure 5(a) for $p_1 > p_2$, average costs for both products increase continuously (from p_2F/p_1k to F/k for Product 1 and from F/k to p_1F/p_2k for Product 2) as q_1 increases from zero to K (and q_2 decreases from K to zero) The marginal cost is positive and increasing from p_2F/p_1k to p_1F/p_2k over the same ranges giving convexity of total allocated costs in Figure 1.

When quantity a_1 of product 1 is produced, the per-unit costs for Product 1 and 2 are given by ordinate c_1 and c_2 respectively in Figure 5(a) (c_1 and c_2 are equal to the tangents of X_1Ok and $X_1O'k'$ respectively in Figure 3). The weighted average of these unit costs, with weights a_1 for c_1 and $a_2 = k-a_1$ for c_2 is easily seen to be equal to F/k from equations (7) and ([illegible]) and this weighted average is given by dotted horizontal line. When product mix is changed by increasing the quantity of 1 from a_1 to a'_1 <u>both</u> average costs increase (from c_1 to c'_1 and from c_2 to c'_2) but their weight average remaines unchanged at F/k since the relative weights have shifted in favor of Product 1 which has lower average cost.

Similarly, in Figure 5(b) when $p_1 < p_2$, the per-unit costs for each product mix decline with a shift in product mix in favor of Product 1 but the weighted average cost remains unchanged at F/k. Thus the choice of allocation basis determines whether the unit costs increase or decrease. The sign of change is the same for both products and this sign cannot be used to draw inferences about the efficiency of the production process itself.

In Figure 5 marginal and average cost curves are convex and approach the horizontal dotted line at F/k as the ratio p_1/p_2 approaches unity. This implies that the apparent paradox of allocated costs will appear only when the number of units of basis resource used in making one unit each of various products is unequal. More formally, Ijiri has worked out the necessary and sufficient conditio for occurance of the paradox, which appears in the appendix.

Generalization of Results

For the sake of simplicity, the above results were given for fixed indirect costs and constant sum of the units of two products. When the indirect costs, I, and the outputs of the two products are allowed to vary in any manner, the sign of change in the unit costs for both products due to a change in output is still the same. Whether the change in unit costs due to a small increase in output q_1 is positive or negative depends on whether

---

$$(10) \quad \frac{p_1 \frac{dq_2}{dq_1} + p_2}{q_1 p_2 + q_2 p_1} \text{ is less than or greater than } \frac{dI(.)}{dq_1} \Big/ I(.)$$

In the simplified example above, $\frac{dq_2}{dq_1} = -1$ and $\frac{dI(.)}{dq_1} = 0$; thus the criterion (10) takes the form of $(p_2 - p_1) <$ or > 0. Note that this condition can be used to determine the sign of change in unit costs caused by any incremental change in the quantity of product 1. Further, the condition can be used to determine the sign of change in unit costs allocated on the basis of any resource used in production (as long as p_1 and p_2 are known) irrespective of whether indirect cost I(.) is dependent on that resource. Of course, the manager may not find the cost allocations based on resources which do not appear in function I(.) very useful. If costs are allocated on the basis of quantity of product itself measured in identical units, we can use $p_1 = p_2 = 1$ for a dummy resource in which case the apparent paradox of unit costs disappears

Although the three examples of Simpson's Paradox given above (the medical, accounting and chips in the box) reflect the same phenomenon. The implications of reversal for decisions based on the data are quite different. For the medical example, the new treatment is truly better than the standard (assuming sampling frequencies are representative of the underlying population distributions), and the decision to select a treatment on the basis of disaggregated data is better than the decision on the basis of aggregated data. For chips in the box example, the objective of maximising the probability of drawing a black chip is maximized by selecting box 1 over 2, 3 over 4 and (2 + 4) or (1 + 3). A different level of aggregation results in different decisions, and, unlike the medical example, there is no single right decision. In the accounting example, neither the aggregated nor the disaggregated data tell us much on which we can base our decision to reward or admonish the production foreman.

Implications for Cost Control

Paradoxes are more than just logical curiosities since they play upon the darker regions of intuition and can, perhaps, be used to sharpen our intuition through derivation of new rules of thumb. In earlier sections we saw that, as long as the rate of utilization of basis resource (p_1 and p_2) remains unchanged, a change in per-unit allocated costs brought about by any change in output, product mix or indirect costs, must have the same sign for all products. [5] The inverse of this proposition is important for managers concerned with cost control:

Proposition: If the sign of change in per-unit allocated costs for all products is not the same, the units of basis-resource required to produce each unit of one or more products must have changed.

In other words, similarity in the sign of change in allocated per-unit costs is the norm and whenever the sign is not the same, it provides the manager with a valuable clue to the changing cost-quantity relationships that may need further investigation. Not all such changes will be revealed by the difference in sign of changes in unit costs; the necessary and sufficient condition for opposite signs of changes in unit costs is

$$N_2^2/N_2^1 \gtrless I^2/I^1 \gtrless N_1^2/N_1^1$$

where N_i^t = units of product i that could be produced from basis resource actually used in period t

I^t Total costs to be allocated between products in period t.

In the Stalcup Paper case, the rate of utilization of basis resource, direct labor, has remained unchanged over the two years and therefore the sign of change in per-unit allocated costs for two products will always be identical, irrespective of what the total indirect costs and the quantities produced are. Because the choice of allocation basis and the rate of utilization of basis resource have such major effect on per-unit allocated costs it is reason enough to issue yet another call for vigilance in interpreting allocated cost data. Conversely, the allocated per unit costs, since they are computed and reported so often, can be used as a means of monitoring the rate of utilization of the resource used as the basis of cost allocation.

FOOTNOTES

1 I am grateful to Professor William W. Cooper and Richard Vancil for bringing this case to my attention.

2 Numbers in this example are taken from the Stalcup Paper case after rounding off, changing the scale and some simplification to eliminate extraneous factors.

3 This assumption of fixed indirect cost is relaxed later to provide more general results.

4 If the quantity of production, measured in comparable units, is used as the basis of allocating costs, we can consider this to be an allocation on the basis of a dummy resource with $p_1 = p_2 = 1$.

5 The proposition can be checked by comparing the signs of the partial derivatives of c_1 and c_2 (in equations (7) and (8)) with respect to parameters p_1, p_2, q_1, q_2, F and $k = q_1 + q_2$. Partial derivatives with respect to p_1 and p_2 are the only ones that have different signs for c_1 and c_2.

APPENDIX

Ijiri's Necessary and Sufficient Condition for Simpson's Paradox

Let $0 \leq p.q.r.s \ngtr 1$, $p > r$, $q > s$, and, without loss of generality, $p \geq q$. Then, Simpson's Paradox occurs if

(A1) $$up + (1-u)q < vr + (1-v)s$$

Where $0 < u$, $v < 1$. The necessary and sufficient condition for the existence of u and v such that (A1) holds is

$$r > q.$$

roof (Necessity): $q \leq up + (1-u)q$ by definition (equality iff p=q). Similarly, $vr + (1-v)s \leq \max(r,s)$ by definition (equality iff r=s). Hence, from (A.1), $q < \max(r,s)$. But $q > s$. Hence, $q < r$.

Sufficiency) If (A 2) holds, select t such that $r > t > q$ and let $u' = (t-q)/(p-q)$ and $v' = (t-s)/(r-s)$. Then (A.1) is satisfied

(a) for u=u' and any $v > v'$: because

$up + (1-u)q = u'(p-q) + q = t$ while

$vr + (1-v)s = v(r-s) + s > V'(r-s) + s = t$

(b) for v=v' and any $u < u'$: because

$vr + (1-v)s = v'(r-s) + s = t$ while

$up + (1-u)q = u(p-q) + q < u'(p-q) + q = t$
